Abstract

Background: Noninvasive and child-friendly biomarkers are important tools for understanding the various phenotypes of childhood asthma.

Objective: The aim of this study was to examine the usefulness of salivary surfactant protein (SP) D in assessing the pathophysiology of childhood asthma.

Methods: We measured salivary concentrations of SP-D and forced oscillation technique (FOT) indexes in 19 healthy controls and 21 asthmatic children. Regression equations for the predictive values of FOT indexes were generated from healthy controls. We analyzed the correlations between salivary SP-D concentration and percentages of the predictive values of FOT indexes, as well as the severity of exacerbation.

Results: We found that salivary SP-D levels were higher in asthmatic children than in healthy controls. In the asthmatic children, salivary SP-D levels correlated with the percentages of predicted differences in resistance between 5 Hz and 20 Hz (%R5-R20), which represented the resistance of peripheral airways, and with the severity of asthma exacerbation.

Conclusion: Salivary SP-D may reflect asthmatic inflammation in peripheral small airways and may be a useful marker for monitoring the degree of exacerbation in childhood asthma.

Key words: Asthma. Biomarkers. Children. Forced oscillation technique. Salivary SP-D.
Introduction

Bronchial asthma is a common chronic inflammatory airway disease in childhood and is defined by recurrent episodes of wheezing, chest tightness, breathlessness, and cough associated with reversible expiratory airflow limitation [1]. Asthma is a heterogeneous disorder, encompassing various phenotypes that can be categorized based on biomarkers such as induced sputum, exhaled nitric oxide, and lung function [2]. Owing to difficulties in the application of these biomarkers in young children [3], the heterogeneity of childhood asthma and its underlying pathophysiology remain to be clarified. Therefore, noninvasive and child-friendly biomarkers are required.

The forced oscillation technique (FOT) is a noninvasive method for measuring airway resistance and elastance during quiet tidal breathing [4-6]. Unlike spirometry, FOT does not require active cooperation or forced respiratory maneuvers and is thus more suitable for young children. FOT has been shown to be more sensitive than spirometry in identifying disturbances of peripheral airway function and has been successfully used for the assessment of pulmonary function in children who cannot perform spirometry during asthma attacks [7-9]. However, various factors, including age, sex, height, and weight, are known to influence FOT parameters [10-13]. Therefore, standardization of FOT indexes with reference values is essential for accurate data acquisition.

Surfactant protein D (SP-D) is a collectin family molecule that, as a component of the innate immune system, plays an important role in pulmonary host defense [14]. The C-terminal lectin head of SP-D suppresses inflammatory cell activation, whereas the N-terminal collagen tail stimulates dendritic cells and macrophages to phagocytose pathogens and apoptotic cells. SP-D also binds to several allergens, thereby modifying allergic responses in the lung [15-17]. In murine asthma models, SP-D attenuates allergen-induced eosinophilia and Th2 cytokine production, resulting in suppression of airway hyper-responsiveness and remodeling [18]. SP-D levels in bronchoalveolar lavage fluid (BALF) have been shown to correlate with the severity of asthma, airway smooth muscle mass, and reticular basement membrane thickness [19]; serum SP-D concentrations are associated with the degree of bronchial inflammation in allergic patients.

SP-D is secreted from the salivary glands, as well as from type II alveolar epithelial cells and nonciliated Clara cells. [19,20]. Of note, glandular tissues in the minor salivary glands of asthmatics exhibit airway-like inflammation [21]. We took advantage of this fact to develop an easy and noninvasive method of sampling SP-D in the saliva of young children. Salivary levels of SP-D were then correlated with FOT indexes and clinical symptoms. We found that salivary SP-D levels correlated with both peripheral airway resistance and severity of asthma exacerbation.

Methods

Participants

We enrolled 21 asthmatic children and 19 healthy controls in the study, which was performed at University of Fukui Hospital, Fukui, Japan between 2012 and 2014. Asthmatic patients were diagnosed by board-certified allergists based on either of the following criteria: more than 3 episodes of wheeze within the previous year; or a hospital admission due to respiratory failure and wheeze within the previous year. Children who had a history of cardiovascular disease, perinatal abnormality, pulmonary infectious disease, and/or immunodeficiency were excluded. The severity of an acute asthma attack was assessed using the acute asthma intensity research score (AAIRS) [22]. The controls were healthy children who had undergone preoperative evaluations and in whom asthma and other respiratory diseases had been ruled out. After written informed consent was obtained from the guardians, saliva was collected using the SalivaBio Children’s Swab (Salimetrics) according to the manufacturer’s protocol. Briefly, one end of the swab was placed under the participant’s tongue for 5 minutes. The saturated swabs were inserted into the swab storage tube and centrifuged at 1200 rpm for 7 minutes at 4°C. Samples (1-2 mL) were then stored at –80°C until salivary SP-D was measured. Saliva was collected at least 2 hours after the last meal. The study was approved by the review board of the University of Fukui Hospital (IRB 20120117).

Forced Oscillation Technique

Airway resistance at 5 Hz and 20 Hz (R5, R20), reactance at 5 Hz (X5), resonant frequency (Fres), and area of low reactance (ALX) were measured using Mostgraph-01 (Chest Co.). Mostgraph-01 continuously measures respiratory parameters during the whole breath, as well as during the inspiratory and expiratory phases, and detects changes in oscillation frequencies. FOT measurements were taken at the time of saliva collection with the participant in the upright position and wearing a nose clip. During the measurements, the participant’s cheeks were supported by the hands of investigators.

Salivary SP-D Measurement

Salivary SP-D concentrations were measured using ELISA (SP-D DuoSet, R&D Systems) according to the company’s protocol. Briefly, 96-well ELISA plates (AGC Techno Glass Co.) were coated with 100 μL/well of 2 μg/mL capture antibody. After blocking with PBS/1% BSA, 50 μL of standard samples in PBS/1% BSA or nondiluted salivary samples were added to each well. After washing with PBS/0.05% Tween 20, the plates were incubated with 100 μL/well of 0.5 μg/mL detection antibody, and then with 100 μL/well of horseradish peroxidase-conjugated streptavidin (×4000 in PBS/1% BSA). The plates were developed with tetramethylbenzidine peroxidase substrate solution.

Regression Equations for the Predictive Values of FOT Indexes

Linear regression equations for the predicted values of FOT indexes were generated from data collected from the 19 healthy controls. The percentages of predicted FOT values in the asthmatic patients were calculated using regression equations, with age, height, and weight as independent variables.
height. More recently, associations between FOT indexes and other growth-associated factors, such as weight and age, have also been demonstrated [12]. Thus, differences in the FOT indices might be due to differences in growth-associated factors between asthmatics and controls rather than to the presence or absence of asthma. Furthermore, FOT percentages appear to be more useful biomarkers than absolute FOT values.

Since growth-associated factors do not necessarily correlate with each other, we generated multiple variable regression equations to predict R5, R20, R5-R20, X5, Fres, and ALX values as dependent variables using the age, height, and weight of the healthy controls as independent variables (Table 3). The multivariable regression equations for the various parameters in a whole breath demonstrated higher R2 values and coefficients of determination than for those in the expiratory and inspiratory phases (data not shown). Thus, the predictive values of R5, R20, R5-R20, X5, Fres, and ALX in a whole breath were used in the subsequent analysis.

### Statistical Analysis

The data are presented as median (range). Unpaired t tests and the Wilcoxon signed-rank test were used to compare salivary SP-D levels between asthmatic patients and healthy controls and to analyze changes in salivary SP-D levels during asthma exacerbations. Correlations between salivary SP-D values and FOT parameters were evaluated using the nonparametric Spearman rho test. A \( P \) value < .05 was considered statistically significant.

### Results

#### Baseline Characteristics of Healthy Controls and Asthmatic Children

We enrolled 19 healthy controls (male:female, 10:9) and 21 asthmatic children (male:female, 13:8) in the study. The median age was 10 years (range, 5-14 years) in healthy controls and 8 years (range, 5-11 years) in asthmatic patients (Table 1). Sixteen out of 21 asthmatic children were treated with controller medications, and no patients received regular therapy with systemic corticosteroids. According to the Global Initiative for Asthma (GINA) 2016 criteria [23], 14 patients had mild persistent asthma, 6 had moderate persistent asthma, and 1 had severe persistent asthma. Salivary samples were obtained during an acute asthma attack and during the follow-up convalescent period in 7 out of 12 patients who had had at least 1 asthma exacerbation during the study period.

#### Multivariable Regression Equations for Predicted Values of FOT Indexes

Asthmatic children demonstrated higher FOT indices, with the exception of X5, than controls (Table 2). Previous studies have reported an inverse relationship between resistances and height. More recently, associations between FOT indexes and other growth-associated factors, such as weight and age, have also been demonstrated [12]. Thus, differences in the FOT indices might be due to differences in growth-associated factors between asthmatics and controls rather than to the presence or absence of asthma. Furthermore, FOT percentages appear to be more useful biomarkers than absolute FOT values.

Since growth-associated factors do not necessarily correlate with each other, we generated multiple variable regression equations to predict R5, R20, R5-R20, X5, Fres, and ALX values as dependent variables using the age, height, and weight of the healthy controls as independent variables (Table 3). The multivariable regression equations for the various parameters in a whole breath demonstrated higher R2 values and coefficients of determination than for those in the expiratory and inspiratory phases (data not shown). Thus, the predictive values of R5, R20, R5-R20, X5, Fres, and ALX in a whole breath were used in the subsequent analysis.

Salivary SP-D Levels Correlate With R5-R20 in Asthmatic Children

SP-D levels in BALF and serum have been shown to reflect the degree of bronchial inflammation in asthmatics [14,24]. Salivary SP-D levels in asthmatics were higher than in healthy controls (P<.05) (Figure 1). However, we observed no correlation between salivary SP-D levels and the use of leukotriene receptor antagonists (P=.1268) or inhaled corticosteroids (P=.2187).

We next analyzed the correlation between salivary SP-D levels and the percentage of predicted values of the FOT index in all 21 asthmatic children. As shown in Figure 2, salivary SP-D concentrations correlated positively with the percentage of predicted R5-R20 values (P<.05). None of the other FOT indexes were significantly associated with salivary SP-D levels.

Salivary SP-D Concentrations Increased During Acute Asthma Attacks

Shi et al [25] demonstrated that increased peripheral airway indexes of FOT, including R5-R20 and ALX, predict asthma exacerbation. We thus asked whether salivary SP-D levels were associated with the severity of an acute asthma attack, as assessed by AAIRS [22]. As shown in Figure 3A, there was no significant correlation between salivary concentrations of SP-D and AAIRS. However, in each asthmatic child, the SP-D concentrations during an acute asthma attack were higher than during the convalescent period, suggesting that individual changes in salivary SP-D levels reflect a change in asthma severity (Figure 3B). The changes in salivary SP-D levels associated with asthma exacerbation were similar to those observed in other patients who were not originally recruited in this study (data not shown).

Discussion

We generated regression equations for the predicted values of FOT indexes in Japanese children and demonstrated that salivary SP-D levels increased during asthma exacerbations and correlated positively with %R5-R20, a peripheral airway index of FOT. Thus, salivary SP-D might serve as a noninvasive biomarker for monitoring peripheral airway function and exacerbations of childhood asthma.

Previous studies have demonstrated that height is the most significant predictor of all FOT indexes in children;
neither gender nor race appears to be an important covariate [10,11,13]. In this study, age had the largest absolute \( \beta \) value among the independent variables of the regression equations, indicating that it was the most influential predictive variable of almost all FOT indexes. The limited number of normal healthy controls in our study might explain this discrepancy. Since height and weight have also been shown to influence the regression equations in many FOT indexes, we generated

levels (r²=0.2105, there is only a weak correlation between serum and salivary SP-D salivary SP-D levels do not merely reflect serum levels, as most salivary SP-D is produced by the salivary gland. In fact, active transport. SP-D is a 43-kDa hydrophilic molecule, and blood to the saliva by passive diffusion, ultrafiltration, or gland, whereas smaller molecules are transported from the airway inflammation.

levels in asthmatic children might also be caused by small airways [30]. Our findings suggest that elevated salivary SP-D small airways that have a larger blood-air surface than central airway inflammation [24,29]. Increased permeability of the blood-airspace barrier caused by bronchial inflammation may lead to increased serum SP-D in asthmatics, especially in airway inflammation [27]. Historically, however, it has been presumed that R5, R20, and R5-R20 represent the resistances of the whole, central-large, and peripheral-small airways, respectively. In this context, salivary SP-D levels correlated with %R5-R20 but not %R20, suggesting that they are associated with airflow limitation in peripheral airways rather than in central airways.

Serum concentrations of SP-D are used in clinical practice as a noninvasive marker of the permeability or integrity of the blood-air barrier in interstitial lung diseases such as interstitial pneumonia [28]. Serum SP-D has been shown to be elevated in allergic patients with a dual asthmatic response after allergen challenge and more pronounced eosinophilic airway inflammation [24,29]. Increased permeability of the blood-airspace barrier caused by bronchial inflammation may lead to increased serum SP-D in asthmatics, especially in small airways that have a larger blood-air surface than central airways [30]. Our findings suggest that elevated salivary SP-D levels in asthmatic children might also be caused by small airway inflammation.

Most large salivary molecules are produced by the salivary gland, whereas smaller molecules are transported from the blood to the saliva by passive diffusion, ultrafiltration, or active transport. SP-D is a 43-kDa hydrophilic molecule, and most salivary SP-D is produced by the salivary gland. In fact, salivary SP-D levels do not merely reflect serum levels, as there is only a weak correlation between serum and salivary SP-D levels (r²=0.2105, P=.1822). Nonvolatile biomarkers in alveolar fluid can be detected in exhaled breath condensate (EBC). The levels detected in EBC are about 10⁻³-fold less than the levels measured in alveolar fluid. If the same dilution factor is applied to SP-D, EBC might contain a few hundred pg/mL of SP-D. Since the EBC volume collected during saliva sampling is negligible compared with the volume of saliva, contamination of SP-D by EBC in salivary samples would likely be insignificant.

Wallcaert et al [31] reported that asthmatic patients exhibited T-cell and degranulated mast cell infiltration and increased basement membrane thickness in the minor salivary glands and bronchial mucosa, suggesting that activated T cells may elicit airway-like inflammation in the salivary glands. Allergen challenge increased SP-D levels in BALF, which correlated with the degree of allergic inflammation in asthmatic lungs [32]. Animal studies in transgenic mice have shown that IL-4 and IL-13 increase SP-D expression [33]. Hazcru et al [34] reported that allergen exposure increased SP-D protein levels in an IL-4/IL-13-dependent manner, which in turn, prevented further activation of sensitized T cells. The allergic inflammatory mechanisms whereby alveolar cells release SP-D into BALF may also enhance SP-D secretion from salivary glands, resulting in increased salivary SP-D levels in asthmatic patients.

Small airway resistance, as assessed by R5-R20, is associated with bronchial hyperresponsiveness, as measured by excessive methacholine-induced bronchoconstriction [35]. Shi et al [36] reported that children with controlled asthma who have increased peripheral airway indices, such as R5-R20 values, are at risk of losing asthma control. Although we found no significant correlation between salivary SP-D levels and AAIRS, possibly owing to individual variations, our data suggest that changes in salivary SP-D levels may reflect the degree of asthma exacerbation in the individual patient. Based on its correlation with R5-R20, salivary SP-D may reflect asthma control status.

In conclusion, salivary SP-D may reflect asthmatic inflammation in peripheral small airways and be a useful biomarker for monitoring the degree of exacerbation in childhood asthma.
