Abstract

Objective: The aim of this study was to assess the relationship between meteorological and pollution-related variables and the symptoms of patients with seasonal allergic rhinitis due to sensitization to grass pollen during 2 different time periods in Madrid, Spain.

Methods: Between March 23 and December 31 in 1996 and 2009, we carried out a daily count of grass pollen grains (Burkard spore trap) and recorded the rhinitis symptom scores in 2 groups of patients with a history of seasonal allergic rhinitis (n=25 in 1996 and n=23 in 2009). Descriptive statistics of the same variables during the study periods were recorded. Associations between variables were assessed using the paired-samples Wilcoxon test and categorical principal component analysis (CatPCA, SPSS24 package).

Results: The mean symptom score was low in 1996 and moderate in 2009. The 1996 and 2009 CatPCA analysis explained around 66.4% and 70.5% of the variance, respectively. The strongest relationships in 1996 were between symptoms and grass pollen counts (R=0.55) and between temperature and ozone (R=0.63). In 2009, the association between temperature and pollution-related variables was even stronger than in 1996: ozone (R=0.53) and PM10 (R=0.34), with a positive sign in both cases.

Conclusions: The effect of temperature and pollution (mainly ozone, even at lower atmospheric concentrations than in established guidelines for effects on health) may have contributed to the higher seasonal allergic rhinitis symptom score recorded in 2009.

Key words: Grass pollen grains. Pollution. Temperature. Ozone. Categorical principal component analysis.

Resumen

Introducción: El objetivo de este estudio fue evaluar las relaciones de las variables meteorológicas y contaminantes en los síntomas de los pacientes con rinitis alérgica estacional con sensibilización al polen de gramíneas durante dos periodos diferentes en Madrid.

Métodos: Durante el periodo del 23 de marzo al 31 de diciembre de 1996 y 2009, se realizó un recuento diario de granos de polen de gramíneas (Burkard spore trap) y puntuación de síntomas de rinitis en dos grupos de pacientes (n = 25 en 1996 y n = 23 en 2009) con historia de rinitis alérgica estacional. Para describir cómo se relacionan las variables, se realizaron estadísticas descriptivas de las mismas variables en los periodos de estudio de 1996 y 2009, contraste no paramétrico pareado de Wilcoxon y un análisis de componentes principales (CatPCA, SPSS24).

Resultados: El valor medio de la puntuación de síntomas en 1996 fue bajo y en 2009 moderado. El análisis CatPCA de 1996 y 2009 explica aproximadamente el 66,4% y el 70,5% de la varianza, respectivamente. La relación más fuerte en 1996 fue entre los síntomas y los recuentos de polen de gramíneas (R = 0,55), la temperatura y el O₃ (R = 0,63). En 2009, la relación entre la temperatura y las variables de contaminación fue incluso mayor que en el periodo de 1996: O₃ (R = 0,53) y con PM10 (R = 0,34), en ambos casos con un signo positivo.

Conclusiones: El efecto de la temperatura y la contaminación (principalmente O₃, incluso a concentraciones atmosféricas más bajas que las pautas establecidas sobre sus efectos en la salud), podría contribuir a la mayor puntuación de síntomas de rinitis alérgica estacional observada en 2009.

Introduction

As many as 44 types of pollen coexist in Madrid, Spain, although seasonal allergic rhinitis is produced mainly by 4 specific types: Cupressaceae (January and February), Platanaceae (March and April), Poaceae, and Oleaceae (May and June) [1].

Grass pollen is the most allergenic in the area, and up to 88% of patients are polysensitized [2]. Thus, most allergy patients in the center of Spain are sensitized to 4 or 5 different types of pollen, thus implying a longer duration of symptoms throughout the year and greater difficulty when applying pharmacological or prophylactic treatment. In the Alergológica 2015 study, the prevalence of rhinitis (all causes) increased from 55.5% to 62.0% (P < .001) compared with the previous study (2005), and grass pollen grains were the principal allergen implicated, with prevalence increasing from 34.8% to 73.7%. In Madrid, this increase was from 61.9% to 87.1% [3]. The age range most affected by seasonal allergic rhinitis is 25-34 years. Consequently, the disease mainly affects young adults, although the overall range is very wide, affecting patients of practically any age [3].

Climate change is increasing the length and intensity of the pollen season, with a significant impact on the millions of patients who already have allergies [4]. Increasing temperatures lead to earlier and longer pollen and allergy seasons, with more frost-free days and earlier and longer flowering seasons [5,6]. Higher temperatures also increase ozone production, which sensitizes the respiratory tract to allergens [7]. Higher carbon dioxide levels cause greater plant growth, resulting in increased pollen production and increased pollen potency [8]. More fall-winter precipitation further contributes to increased pollen production [9].

The aim of this study was to assess the relationships between meteorological and pollution-related variables and the symptoms of patients with seasonal allergic rhinitis due to sensitization to grass pollen during 2 different time periods in Madrid.

Material and Methods

During the periods March 23 to December 31, 1996 and March 23 to December 31, 2009, we carried out the following studies:

- Daily grass pollen count using a Burkard collector (Clinica Subiza, Madrid), as previously described [1]. The main pollen season ran from the first date with 10 grains/m³ on 3 consecutive days until the date of the last 3 consecutive records at the same level.
- Daily measurement of meteorological data (temperature, rain, humidity, wind speed) using data from Barajas-Madrid station (National Meteorological Agency).
- Daily measurement of pollution (ozone, CO, SO2, NO2, PM10) from the Escuelas Aguirre station (Madrid City Council).

*Significant differences (P < .000, nonparametric paired samples Wilcoxon test) were found for all variables except temperature.
skin prick tests. The mean age of patients was 30.95 (range, 16-47) years, and all patients (100%) were sensitized to grass pollen (with wheals of 4+ \(AR > AH\): \(AR\) = resulting area in mm\(^2\): allergen area – saline area; \(AH\) = histamine area – saline area) and to Oleaceae, Platanaceae, and Cupressaceae pollen grains (43.5%, 30.4%, and 56.5%, respectively, with smaller wheals: 2+ to 3+). Two of the patients (2009) were sensitized to \textit{Dermatophagoides pteronyssinus} and 4 (2009) to cat dander, although the sensitization was not clinically relevant. Nasal symptoms (sneezing, itching, congestion, and rhinorrhea) were assessed in patients clinically sensitized to grass pollens in the previous 2 years. A daily electronic card was completed on a daily basis with the following scale: 0, absence of symptoms; 1, mild symptoms; 2, moderate symptoms; and \(\geq 3\), severe symptoms.

Results

Total yearly grass pollen counts in 1996 and 2009 were 6588 grains/m\(^3\) and 2556 grains/m\(^3\), respectively (seasonal maximum counts: June 1, with 552 grains/m\(^3\), and May 11, with 121 grains/m\(^3\), respectively). The main pollen seasons lasted from May 13 to July 9 and from May 2 to July 11, respectively.

The Table includes descriptive statistics for all variables for both years, highlighting significant differences \((P=0.000)\) based on the paired-samples Wilcoxon test, especially for symptoms. The exception was for temperature. This study is limited by the nonavailability of the trend in the variables studied over the years, although the temperature in Madrid has tended to increase over the last 38 years, with temperature increases of 1.4ºC during May-July from 1979 to 2016 (ie, 0.36ºC per decade) \[11\].

Figure 1 shows plots of the main variables studied during both time periods; the samples show that increases in grass pollen grain counts are accompanied by increases in the symptom score (mean value for 1996, low score; mean value for 2009, moderate score). The CatPCA analysis explains around 66.4% of the variance in 1996 and 70.5% of the variance in 2009. In both cases, these percentages account for the relationships between the variables.
In the 1996 CatPCA analysis, symptoms were related mainly to grass pollen (R=0.55) and, to a lesser extent, to temperature (R=0.38) and ozone (R=0.28); all relationships had a positive sign (Figure 2). With PM10, the correlation coefficient was much lower (R=0.18). Temperature is related to pollen counts, symptoms, PM10, and ozone (the correlation is particularly strong for ozone, R=0.63). Given the position and proximity of the lines on the graph, the variables with the closest association are symptoms and grass pollen counts (R=0.55) and temperature and ozone (R=0.63). In both cases, the relationships are positive, meaning that high values in one parameter correspond to high values in the other, i.e., higher pollen levels, higher symptoms, higher temperatures, and higher ozone levels. Temperature is also clearly related to symptoms and PM10 (R=0.34 and R=0.33); the sign for this relationship is also positive. Consequently, high temperature levels are related to high values for symptoms and PM10. Values for the association between temperature and grass pollen counts are much lower, although the sign continues to be positive (R=0.28).

Also noteworthy is the weak association between the pollution variables ozone and PM10, which, therefore, occupy distant, almost perpendicular positions on the graph. In addition, this relationship has a negative sign (high levels of PM10 reduce ozone levels).

The 2009 CatPCA analysis (Figure 3) explains 70.5% of the variance. The relationship between symptoms and pollen becomes stronger (R=0.81) and remains positive, as does that of ozone, albeit to a lesser extent (R=0.35), with both coefficients higher than in 1996.

The difference between the analyses for 2009 and 1996 is in the association between the allergy variables and the rest of the variables (as can be clearly seen in the positions occupied by the variables on the graph). In contrast to the 1996 period, the 2009 variables (symptoms and grass pollen counts) are associated mainly with ozone (R=0.35, R=0.26). Therefore,
Discussion

We found a higher symptom score in the 2009 period, despite lower pollen counts, than in the 1996 period. However, it is important to remember that this was a year with lower humidity, similar temperatures, and higher ozone levels (albeit lower than threshold). Consequently, these factors may have affected the longer duration and intensity of the grass pollen season that year. The specific atmospheric conditions in Madrid in spring, where marked instability leads pollen deposited on the ground to be lifted, may also have contributed.

In southern Spain, the grass pollen season is now longer as a result of rising temperatures [12]; the same is true for the Oleaceae pollen season [13]. The increase in temperature in this geographical area seems to have a positive effect on the intensity of flowering, with longer pollination periods that are often more intense. In this study, the main pollen season in 2009 was 13 days longer than in 1996. The grass pollen forecast in Madrid is always announced by March. Rainfall from October 1995 to March 1996 in Madrid was twice that of the previous period (October 1994-March 1995), thus leading to a 4-fold higher number of grains in 1996 than in 1995. Furthermore, the Spanish Society of Allergy and Clinical Immunology (SEAIIC) estimated that the cumulative concentrations of grass pollen counts in 2009 exceeded 5100 grains/m³, compared with 4000 grains/m³ recorded in 2008. Nevertheless, the lower grass pollen counts collected in 2008 were probably due to the cleaner rain effect observed in May, which coincided with the peak grass pollen period (Figure 1), albeit in a more polluted atmosphere and with more allergenic activity, as shown by the higher seasonal allergic rhinitis score.

We suggest that this finding could be associated with the coadjuvant effect of temperature and pollution (mainly ozone), which generates more potent allergens, as well as with the direct relationship between the greater level of atopy in the 2009 group than in the 1996 group. Ozone increases allergenicity (induces larger wheals and flares in skin prick tests) [14], and exposure of Phleum pratense pollen to increasing ozone concentrations (from 100 ppb up to 5 ppm) results in a significant increase in naturally released pollen cytoplasmic granules, which also contain allergens [15].

Pollution is a possible cause of oxidative stress, and this stress is responsible for the higher prevalence of seasonal allergic rhinitis, which intensifies in activity as a defense from environmental pollution, thus strengthening allergenicity [16]. Pollutants such as SO₂, NO₂, and ozone can alter the allergenic proteins of pollen [16,17].

Ozone is a pollutant that usually reaches higher values in areas far from the sources of emission, that is, in semiurban and rural areas. The atmospheric conditions present in heat waves favor the formation of tropospheric ozone from precursors [18]. During the summer, the excessively high temperature in Madrid (higher than the threshold of 36.5°C) coincides with the days on which the population must be warned about high concentrations of ozone (higher than the threshold of 180 μg/m³) [18]. These thresholds were not exceeded in 2009, although mean annual values tended to increase [19]. In Madrid in 2017, the number of times the ozone threshold was exceeded (>25 times) was recorded in the 2011-2017 report [20]. As ozone is a secondary pollutant, the measures adopted were aimed at reducing the emission of precursors, mainly NOx and volatile organic compounds [18]. In a recent report from Ecologistas en Acción (2018), 2 of the stations measured high ozone values in winter that were similar to those recorded in spring in the same places (San Agustín de Guadalix and Puerto de la Morcuera), namely, 70 and 80 μg/m³ [21]. With regard to photochemical pollutants or the synergistic effect of ultraviolet radiation on pollutants, study of the effects of UV-B rays and ozone shows that the pollen tube was shortened considerably, more than by the stress itself, despite low levels of ozone [22].

Differences have been found in the allergenicity of pollens from groups of trees of the same species and grass pollen, which, although relatively close in terms of taxonomy, are found in areas with different pollution levels (city/countryside) and temperatures (valley/mountain) [23]. In Spain in 2002, Armentia et al [23] reported that the grass pollen in rural areas of the province of Valladolid was less damaged than the same species in urban areas, where grass pollen is subject to a polluted environment, repeated mowing that lets very few spikes flourish, and pesticides applied by local authorities [23]. In 2007, Feo-Brito et al [24] reported that the air pollution levels in Puertollano (high pollution levels) were associated with a greater risk of asthma symptoms in pollen-allergic asthmatic patients than in a similar group from Ciudad Real (lower pollution levels) [24]. The largest contribution was by ozone, especially in Puertollano [24]. In 2007 and 2010, Mur Gimeno et al [25] and Feo-Brito et al [26] reported that pollen-allergic asthmatics in Puertollano presented poorer clinical progress and became decompensated earlier than those from Ciudad Real, and that this could be due to air pollution. Consequently, urbanization and high levels of vehicle emissions induce more symptoms of bronchial obstruction (in particular bronchial asthma) in people living in urban areas than in those living in rural areas.

In the eastern United States and Europe, the highest regional ozone levels are recorded when a slow-moving, high-pressure system develops in summer. This is when the days are longest, when solar radiation is most direct (the solar zenith angle is lower), and air temperatures are high. As the slow-moving air in the shallow boundary layer passes over major metropolitan areas, precursor concentrations rise; as the air slowly flows around the high-pressure system, photochemical production of ozone occurs at peak rates [27]. We suggest that high temperatures in Madrid, even with low levels of ozone concentrations (which was higher 13 years later), could be a factor that has contributed to the increase in symptoms even at lower grass pollen counts in 2009 than in 1996.
Ozone levels are mostly higher in rural areas than in cities. Ozone is degraded by NO, which is also involved in its formation. This degradation occurs more often in cities than in rural areas, because there is more NOx in cities. For this reason, ozone concentrations are higher in rural areas than in cities [27].

According to the review of evidence on health aspects of air pollution in the REVHAAP Project (Technical Report) (2013) [28], the European threshold of 180 µg/m³ for informing the population may thus not be viewed as an effective threshold value under which absolutely no one will experience any effect at all. However, the World Health Organization (WHO) postulated that the effects of concentrations lower than 200 µg/m³ will be limited in severity and will only prevail in less than 5% of the total population [29]. Warning the whole population at lower concentration levels is therefore not advised. As such, the threshold values can be considered a sliding scale, and—albeit somewhat artificially—it is possible to talk about a mild response at (hourly mean) concentrations of 180-240 µg/m³, a moderate response at 240-360 µg/m³, and a severe response above 360 µg/m³ [28, 29]. The review concludes that a considerable amount of new scientific information on the adverse health effects of particulate matter, ozone, and NO₂ observed at levels commonly present in Europe in recent years [28]. This new evidence supports the scientific conclusions of the WHO air quality guidelines, last updated in 2005, and indicates that, in some cases, the effects occur at air pollution concentrations lower than those serving to establish these guidelines [29].

Pollution particles also contain diesel exhaust particles. At present, 70% of all particles and 90% of those <5 µm (respirable particles) are produced from its combustion, which induces important biological changes, such as a more marked TNF response [30, 31].

The increasing frequency of obstructive respiratory diseases during recent years, in particular allergic asthma, can be partially explained by changes in the environment, with the increasing presence in the atmosphere of chemical triggers (particulate matter and gaseous components such as NO₂ and ozone) and biologic triggers (aeroallergens). Consequently, measures need to be taken to mitigate the future impact of climate change and global warming [32]. Over the last 50 years, the earth’s temperature has risen markedly, likely because of growing concentrations of anthropogenic greenhouse gas [32]. For this reason, it is important to emphasize to patients that climate change is increasing exposure to allergens and suggest what they can do to minimize their exposures and thus reduce allergy and asthma symptoms, such as checking pollen levels frequently. In Spain, patients can sign up for free alerts from the Spanish Society of Allergy and Clinical Immunology Aerobiology Network. For patients with asthma, it is important to check ozone levels.

**Conclusions**

The effect of temperature and pollution (mainly ozone, even at lower atmospheric concentrations than those established in guidelines about its effects on health) could contribute to the higher seasonal allergic rhinitis symptom score observed in 2009.

We highlight the need to continue research into the impact of these changes and into strategies and policies to reduce greenhouse gas emissions and air pollution.
